Evidence for Transverse Dependencies in COTR and
Microbunching in a SASE FEL*

Abstract

Using coherent optical transition radiation (COTR) techniques, we have observed transverse dependencies, which in some aspects relate to the electron beam microbunching in a visible wavelength (540 nm) self-amplified spontaneous emission (SASE) free-electron laser (FEL). The experimental COTR observations include the z-dependent e-beam sizes, the z-dependent angular distributions, and the z-dependent spectra (which show an x-dependence). A 30-40% narrowing of the observed beam size using COTR is explainable by the mechanism's dependence on the square of the number of microbunched particles. However, additional effects are needed to explain beam size reductions by factors of 2-3 at different z locations. Localized e-beam structure in the gun or induced in the bunch compression process may result in microbunching transverse dependence, and hence the observed COTR effects.

Introduction

The basic models of electron-beam microbunching in a self-amplified spontaneous emission (SASE) free-electron laser (FEL) describe the density modulation in the longitudinal distribution of the micropulse at the fundamental wavelength of the FEL [1-4]. While observation of the spectral enhancement in coherent transition radiation in a SASE FEL was reported at 13 μm [5], the actual observation of the variation of the modulation and microbunching fraction with peak current along the micropulse time profile has been observed only in an infrared oscillator experiment to date [6]. However, we have observed in our 540-nm wavelength SASE FEL transverse dependencies of coherent optical transition radiation (COTR), which in some aspects imply transverse microbunching phenomena [7,8]. In our measurements the longitudinal information is integrated by the detectors. Our experimental observations include the z-dependent e-beam sizes obtained by using a 500-nm short pass filter to select broadband OTR versus the narrow-band COTR emitted at 530 nm, the FEL fundamental. We can explain a 30-40% narrowing of the observed beam size using COTR by its intrinsic dependence on the square of the number of particles. However, additional effects are needed to explain the beam size reductions by factors of 2-3 at some z locations. Localized beam structure or an “effective core” in some parameters is predicted as a result of bunch compression in a chicane due to coherent synchrotron radiation (CSR) effects. Such a beam core would be reflected in the COTR intensity distributions. In addition to the near-field imaging, we report the complementary evidence from the far-field COTR interference images and the evidence from the imaging spectrometer for x-dependent spectra. Relevant information from GENESIS simulations and the ELEGANT particle tracking code are also discussed.

Experimental Background

The experiments were performed at the Advanced Photon Source (APS) low-energy undulator test line (LEUTL) facility [9]. A schematic of the facility is provided elsewhere in these proceedings [10]. These experiments used the photocathode (PC) rf gun, the S-band linac, the chicane bunch compressor [11], and the LEUTL hardware.

The diagnostic stations located before and after each station have been described previously [12]. For these experiments we used the 45° pick-off mirror at each station to direct the SASE radiation to the visible light detectors (VLDs) consisting of a CCD camera with up to three filter wheels. These filter wheels provided the appropriate bandpass (BP) filters and neutral density (ND) filters to keep the video signals out of saturation as one measures the dramatic z-dependent signal intensity growth due to the SASE process. Also, the 500-nm shortpass (SP) filters were installed at each station to sort OTR versus COTR signals. Both near-field and far-field imaging options were available via a remote-controlled translation stage that changed the camera-to-lens separation appropriately. For completeness, the schematic of the diagnostic station is shown in Fig. 1. The COTR experiments were performed by inserting the appropriate 6- μm -thick Al foil via the actuator 63 mm upstream of the 45° pick-off mirror. This foil both blocks the intense SASE light component and generates COTR for the interferometer experiments.

An additional capability involved the installation of a full set of mirror pairs and UV-visible lens pairs after each undulator. As seen in Fig. 2, a retractable mirror could be used to direct light into this transport optics and onto the Oriel M257 UV-visible spectrometer located in the tunnel. The lens pair was located at ~ 1.34 m from the in-

vacuum 45° mirror. The lenses had a separation of 36 mm at each station for 540-nm experiments. In practice this is an imaging spectrometer, so the 2-D information recorded by the readout camera involves wavelength on the horizontal axis and the x- or y-spatial profile on the vertical axis. For our optics we see the x-spatial profile. This system has been used to detect the production of sidebands [8] and the mode size change after SASE saturation, but it also was used to evaluate $x-\lambda$ effects in the present experiments. An alignment laser beam at 543.5 nm wavelength was sent into the chamber bore in front of the first undulator, and the switching mirrors were used to verify light transport at all ten pick-off points. For a spectrometer entrance slit of 50 μm , a limiting resolution of ~ 0.9 nm (FWHM) was attained. The spectrometer functions were under EPICS control. By illumination of a 600- μm -diameter reference hole at the 45° mirror position, the optics was adjusted to center this feature in the entrance slit.

Experimental Results and Discussion

We now present results from the near-field imaging, far-field imaging and the spectrometer. We have previously reported what appeared to be effects on the transverse COTR intensities in beam size [13] and the far field [8], but for those experiments the 500-nm shortpass filters had not been installed in the filter wheels, so the sorting of OTR and COTR contributions at low gain was difficult.

Near Field Results

The near-field focus position of the camera/lens combination provides beam size and profile information. In our geometry we can evaluate electron beam information at the 45° mirror by eliminating the intense SASE light with the thin Al blocking foil located in the upstream actuator position at each station. The calibration factors for the VLD 1-8 stations were 80 $\mu\text{m}/\text{ch}$ and 90 $\mu\text{m}/\text{ch}$ for the x- and y-planes, respectively. We operated with a reduced peak current of 120 A (see Table 1) to limit the gain and the microbunching factor because we initially only had a single 500-nm shortpass filter available to attenuate by 100 the 530-540 nm fundamental COTR intensity. Examples of the z-dependent e-beam sizes are shown in Fig. 3. The upper figure shows the x-sizes in channels and the lower figure shows the y-sizes. For the VLD 5-8 stations, the data were taken as 100 images each with one 500-nm SP filter (OTR imaged, circles) and without this BP filter (COTR imaged, squares). In the latter case the appropriate ND filter was selected to keep the camera out of saturation. A dramatic measured beam size difference (> factor of 2) was observed between the OTR case and the COTR case at VLD 5. Systematically, the no-BP filter COTR case is smaller than the filtered case for the next three stations as well. As seen in Fig. 4, the integrated image intensities exhibit the exponential gain growth signature beginning at VLD 5. Both the SASE (upper) and COTR (lower) intensities show little gain (hence little microbunching) at VLD 1-4. (These gain curves also suggested an undulator alignment problem had developed with the settling of the concrete floor as subsequently verified by the survey team.) We have now taken some data with two shortpass filters in series at each station to improve the rejection of the microbunching component in the beam size measurement. These results

were consistent with our initial test, but allowed us to sort the COTR signals at even higher gains.

We have performed a calculation of the beam image spot narrowing that occurs when COTR is used as the conversion mechanism. If the bunching fraction is assumed to be uniform across the Gaussian-shaped transverse dimension, then the $(b_n N)^2$ term (where b_n is the microbunching factor for harmonic component n and N is the number of electrons in the micropulse) for the peak intensity will approximately give a $\sqrt{2}$ narrowing of the “observed” peak. In the GENESIS simulations [14] the bunching fraction is found to be uniform across the transverse dimensions for a time-slice sample when a smooth Gaussian e-beam distribution is used as input.

Far-Field Results

The camera-to-lens z separation can also be selected for far-field imaging. In this case the angular distribution patterns of the radiation are obtained. Based on the analytical model described in Ref. 15, the single-electron OTR interference (OTRI) pattern for two sources 63 mm apart is first calculated. This includes effects due to beam divergence. The calculated OTRI pattern exhibits fringes at $\theta = \pm 1.9, \pm 4.6, \pm 6.3,$ and ± 7.5 mrad. The bunch form factor is multiplied times this pattern. Larger beam sizes ($> 100 \mu\text{m}$) have relatively narrow form factor functions in θ space. Figure 5 shows examples of the COTR fringe visibility variation with e-beam size. The COTR second fringe peaks are visible for beam sizes less than $50 \mu\text{m}$, such as $25 \mu\text{m}$ in Fig. 5. The observed first fringe peak position varies with beam size for $\sigma > 100 \mu\text{m}$. An example of

an image is given in Fig. 4 of Ref. 8. In that case, the relative intensities of the fringe peaks implied $\sigma_y = 30 \mu\text{m}$ with total divergences of 0.2 mrad (which would include the ~ 0.1 mrad scattering contribution from the Al foil). The $\sigma_y = 30 \mu\text{m}$ result is smaller than the limiting resolution value of about one pixel at $90 \mu\text{m}/\text{pixel}$ for the near-field focus. As can be seen from Fig. 5, asymmetric beam sizes of $\sigma_x = 100 \mu\text{m}$ and $\sigma_y = 30 \mu\text{m}$ would give completely different fringe patterns in θ_x and θ_y . That is what was observed. In the case of the well-aligned FEL experiment previously reported [8], we noted the outer fringes were visible early in the gain process and in postsaturation, but not at saturation. These results are consistent with a beam core being initially involved in the microbunching. This core grows in transverse size up to saturation and then reduces to a residual core in the post saturation regime of this experiment. A debunching effect after the undulator regime that gives a residual core has been reported in an FEL amplifier experiment [16].

Imaging Spectrometer Results

The imaging spectrometer provides a complementary view of the situation. Due to the lower detection efficiency of this system, predominately COTR is seen since the broadband OTR is so much weaker. The microbunching fundamental wavelength is clearly evident in the $x-\lambda$ images in Fig. 6 where the horizontal axis is wavelength and the vertical axis provides the x profile information. For the beam conditions given in Table 1 for the 300-A peak current, we clearly see structure in both dimensions in the $x-\lambda$ image obtained after undulator 6. Most striking is the fact that the two spatial clusters separated by $\sim 120 \mu\text{m}$ emit at two different wavelengths (2.9 nm apart). The beam size features in x are about $280 \mu\text{m}$ (FWHM) or $\sigma_x = 120 \mu\text{m}$. This is a factor of two lower than the

theoretical beam-matched value for $\beta_x = 2.7$ m and $\varepsilon_x = 8$ mm mrad. The complementary near-field measured x-beam size with VLD 6 was 240 μm (FWHM) averaged over 100 images. We have looked at ELEGANT simulation results of the beam after bunch compression in the chicane [17]. These simulations show some structure in the x distribution and some energy encoding in the bend plane, although this generally occurs at a higher compression than that of our 300-A case. Such a phenomena would be preferentially selected in the SASE process when higher 6-dimensional charge densities are involved. At some point the detailed experimentally determined distributions and/or ELEGANT-calculated distributions should be input to GENESIS to explore these effects.

Summary

In summary, we have discussed the growing evidence for transverse dependencies in the microbunching of electron beams in a SASE FEL. We have used complementary views into the beam distributions and intensity structure with near-field and far-field imaging coupled with the correlated x - λ views. We propose that the SASE FEL mechanism selectively interacts with the favorable cluster of beam induced in the chicane bunch compressor of our experiment. We also propose that the bunching fraction may vary within the electron beam transverse distribution during the exponential growth phase and in the debunching phase of our experiments.
